

## Cancer Genomics: Chapter 12. Genomics and Molecular Profiling of Lung Cancer

Lung cancer remains the leading cause of cancer-related death worldwide. Although surgical resections of these tumors are considered as one of the most effective treatments, most lung cancer patients present at an advanced stage of the disease at the time of diagnosis and are not candidates for surgical resection. Overall, the prognosis of lung cancer is very poor and the 5-year survival rate is only about 16 %, which has not significantly changed in the past several decades. Therefore, seeking new directions of treatment for this most deadly disease becomes crucial. Recent development in the understanding of the molecular pathogenesis of lung cancer has led to new strategies of treatment. Development of lung cancers is thought to be driven by gene mutations in most, if not all, cases. Detailed analysis at the molecular level to identify these gene mutations or alterations in lung cancer provides the insight for understanding the disease and is fundamental for establishment of personalized targeted therapy. Personalized targeted therapy based on particular gene mutations has shown to be effective and is believed to be one of the new directions of the treatment in dealing with this disease. In modern oncology, there is an increasing need to facilitate the development and implementation of biomarkers based on known gene mutations/alterations in clinical practice and identification of new gene mutations/alterations through high-throughput DNA sequencing technology to enter a new era of personalized targeted therapy for lung cancer patients.
